Scale-Dependent Dimensionality Profiles Across Neural and Synthetic Representations

April 2026

Abstract

We analyzed effective dimensionality as a function of neighborhood scale across five representational systems. Effective dimensionality follows a consistent growth–saturation profile: locally low-dimensional structure expands with increasing neighborhood size before reaching a bounded plateau. After within-system normalization, dimensionality curves exhibit strong cross-domain alignment (mean Pearson $r \approx 0.90$, corresponding to approximately 81% shared variance). Systems differ quantitatively in growth rate (range: 0.23–0.82) and saturation behavior. Model-derived cortical representations (TRIBE) show pronounced compression ($D_{\text{eff}} \approx 3$–5, compression ratio = 0.49) and early saturation relative to synthetic systems.

Extensive negative controls–including dynamical torsion, curvature, and residual structure analyses (V8–V12)–fail to reproduce robust alignment, indicating that the observed pattern is not attributable to specific dynamical or statistical artifacts. A null model with matched eigenvalue spectrum partially reproduces the growth–saturation profile but shows weaker alignment with other systems, suggesting some aspects may reflect general statistical structure while others remain system-specific. These findings are descriptive and do not establish a mechanistic origin or generalize beyond the systems analyzed.

1 Introduction

Characterizing the geometry of high-dimensional representations is a fundamental challenge across neuroscience [Kriegeskorte et al., 2008], machine learning [Saxe et al., 2021], and complex systems. In cortical organization, large-scale gradients provide a low-dimensional embedding of functional structure [Margulies et al., 2016], yet the multi-scale organization of representational geometry remains poorly understood.

Most analyses focus on fixed-scale properties, overlooking how local structure expands into global organization [Saxe et al., 2019]. A scale-dependent perspective is required to capture this transition. For instance, while cortical representations may appear low-dimensional at local scales, they may reveal additional structure when examined at broader spatial scales.

Here, we analyze effective dimensionality as a function of neighborhood scale across multiple systems. This allows us to test whether representational systems share common structural patterns and to quantify how they differ. Our approach characterizes each system by its *dimensionality profile* $D_{\text{eff}}(k)$, where k denotes neighborhood size.

We define a "shared normalized multiscale dimensionality profile" as a reproducible, scale-dependent pattern in the relationship between local and global representational geometry that is conserved across systems after normalization. In this context, the motif refers specifically to the growth–saturation profile of effective dimensionality as a function of neighborhood scale, rather than to any particular generative mechanism.

While prior work has examined intrinsic dimensionality and manifold structure in neural and artificial systems, these approaches typically focus on fixed-scale estimates or global embeddings. The present analysis instead emphasizes the scale-dependent evolution of effective dimensionality, providing a complementary perspective that captures how local representational structure expands into global organization. This distinction is critical for identifying shared structural patterns that are not apparent in single-scale analyses.

2 Methods

2.1 Overview

We analyzed effective dimensionality as a function of neighborhood scale across five representational systems: one model-derived representational system (TRIBE cortical model) and four synthetic systems designed to span different geometric structures. All analyses were implemented in Python using NumPy, SciPy, and pandas.

2.2 Datasets

We analyzed the following systems (see Table 1):

- **TRIBE v2**: Model-derived cortical representations using the Sentient Field Hypothesis (SFH) framework mapped to Schaefer-400 parcels [Schaefer et al., 2018]. TRIBE v2 generates cortical activation predictions that were aggregated into 9 cognitive/functional domains corresponding to: Broca, Wernicke, temporoparietal junction (TPJ), prefrontal cortex (PFC), default mode network (DMN), limbic, sensory, anterior temporal lobe (ATL), and premotor systems. This results in a 9-dimensional representation per stimulus. From a total of 11,522 model predictions, a subset of 2,000 samples was selected uniformly at random to match the sample size of synthetic datasets for controlled comparison.

  To ensure fair comparison across systems, we selected 2,000 samples uniformly at random from the full TRIBE dataset of 11,522 predictions. Preliminary analyses with alternative subsample sizes (n = 1000, 3000, 5000) produced qualitatively similar growth–saturation profiles, indicating robustness to subsampling choice.

We emphasize that TRIBE-derived representations are model-based approximations intended to capture structured relationships between cognitive domains, rather than direct measurements of neural activity. Accordingly, results involving TRIBE should be interpreted as reflecting properties of a biologically inspired representational model, not as empirical observations of cortical dynamics.

- **Hierarchical Gaussian**: 2000 samples in 50 dimensions with exponentially decaying variance across dimensions.
- **Correlated Gaussian**: 2000 samples with full covariance structure.
- **Sparse**: 2000 samples with 90% zero entries.
- **Curved manifold**: 2000 samples distributed on a curved manifold embedded in 50 dimensions.

Table 1: Dataset Characteristics

System	N Samples	Ambient Dim	Data Type
TRIBE	2000	9	Cortical model (SGP nodes)
Hierarchical	2000	50	Synthetic (hierarchical Gaussian)
Correlated	2000	50	Synthetic (correlated Gaussian)
Sparse	2000	50	Synthetic (sparse)
Manifold	2000	50	Synthetic (curved manifold)

2.3 Effective Dimensionality (Participation Ratio)

Effective dimensionality was computed using the **participation ratio** (PR), which provides a continuous measure of dimensionality that is robust to noise and eigenvalue spacing:

$$D_{\text{eff}} = \frac{\left(\sum_{i=1}^{d} \lambda_i\right)^2}{\sum_{i=1}^{d} \lambda_i^2} \tag{1}$$

where λ_i are eigenvalues of the covariance matrix, sorted in descending order. The PR ranges from 1 (all variance in a single direction) to d (uniform variance across all dimensions).

Computation pipeline:

1. For each data point, identify the k nearest neighbors using Euclidean distance
2. Construct the local covariance matrix from the k neighbors
3. Perform eigendecomposition: $\mathbf{C} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^T$
4. Compute participation ratio using Equation 1

5. Average D_{eff} across all points

The participation ratio was chosen over alternative metrics (e.g., MLE-based intrinsic dimension) because it is computationally efficient, requires no model selection, and has been validated across neuroscience applications [Kriegeskorte and Kievit, 2013].

Alternative dimensionality metrics, including intrinsic dimensionality estimators and correlation dimension, were explored in preliminary analyses. These analyses produced qualitatively similar growth–saturation profiles, supporting the robustness of the observed pattern to the choice of dimensionality metric.

2.4 Neighborhood Construction

For each system, we computed $D_{\text{eff}}(k)$ across the following neighborhood sizes [Mante et al., 2013]:

$$k \in \{5, 10, 20, 50, 100, 200, 500\}$$

Neighborhood sizes were selected to span regimes from highly local structure ($k = 5$) to near-global sampling ($k = 500$, approximately 25% of the dataset). This range enables detection of both early growth and saturation behavior. Preliminary analyses with alternative spacing produced qualitatively similar results.

Neighborhoods were constructed using Euclidean distance [Ecker et al., 2011]. We chose Euclidean distance for computational efficiency and interpretability in the original data space. Preliminary analyses using cosine similarity and correlation distance produced qualitatively similar growth–saturation profiles (mean alignment r ¿ 0.85), indicating robustness to metric choice.

For each data point x_i, the k nearest neighbors $\{x_j\}_{j=1}^{k}$ were identified, and the local covariance was computed as:

$$\mathbf{C}_i = \frac{1}{k-1} \sum_{j=1}^{k} (x_j - \bar{x}_i)(x_j - \bar{x}_i)^T \tag{2}$$

where $\bar{x}_i$ is the mean of the k neighbors including x_i.

2.5 Normalization

To enable comparison across systems with different absolute dimensionality, we normalized both axes:

$$\tilde{D}(k) = \frac{D_{\text{eff}}(k)}{\max_k D_{\text{eff}}(k)} \tag{3}$$

$$\tilde{k} = \frac{k}{k_{\max}} \tag{4}$$

This normalization preserves the shape of the dimensionality profile while removing system-specific scale factors.

We normalize by the maximum observed D_{eff} within each system rather than ambient dimensionality to isolate the shape of the growth–saturation profile independent of system-specific capacity. Normalizing by ambient dimension would disproportionately amplify differences in sparse systems where $D_{\max} \ll d_{\text{ambient}}$. This approach enables direct comparison of profile geometry across systems.

2.6 Curve Alignment

Similarity between normalized dimensionality profiles was quantified via Pearson correlation on a common grid (20 points spanning $\tilde{k} \in [0.05, 0.95]$):

$$r = \text{Corr}\left(\tilde{D}_1(\tilde{k}), \tilde{D}_2(\tilde{k})\right) \tag{5}$$

where Corr denotes Pearson correlation.

No correction for multiple comparisons was applied to pairwise correlations. Given the high effect sizes observed ($r \approx 0.8$–1.0), results are unlikely to be driven by chance but should be interpreted descriptively.

2.7 Growth Rate Estimation

Growth rate was estimated as the slope of D_{eff} vs. k in log-log space for the early phase ($k \leq 50$):

$$\log D_{\text{eff}} = a + b \cdot \log k \tag{6}$$

where b is the growth rate.

Growth rates were estimated via least-squares fitting in log-log space over the range $k = 5$–50. Across systems, 95% confidence intervals for slope estimates ranged from approximately ± 0.03 to ± 0.08, indicating that observed differences in growth rates are statistically reliable.

2.8 Quantification Metrics

The following metrics were computed for each system:

- **Growth Rate**: Log-log slope in early phase ($k \leq 50$)
- **Saturation Ratio**: $\bar{D}_{\text{top10\%}}/D_{\max}$
- **Compression Ratio**: $D_{\max}/d_{\text{ambient}}$
- **Peak $\mathbf{D_{eff}}$**: Maximum effective dimensionality
- **$\mathbf{k_{peak}}$**: Neighborhood size at peak

Robustness analyses were conducted to assess sensitivity to methodological choices. In particular, the observed growth–saturation profiles were qualitatively preserved across variations in neighborhood size sampling, alternative distance metrics, and dimensionality estimators tested in preliminary analyses. While the participation ratio was selected for computational efficiency and interpretability, its behavior under varying statistical conditions motivates further evaluation using targeted null models.

3 Results

3.1 Scale-Dependent Dimensional Growth

All systems exhibited increasing effective dimensionality with neighborhood scale (Fig 1). Local neighborhoods ($k = 5$) were low-dimensional across all systems, while larger neighborhoods revealed progressively higher-dimensional structure.

Figure 1: Effective dimensionality D_{eff} as a function of neighborhood size k for all systems. TRIBE shows early saturation, while synthetic systems exhibit more gradual growth.

To further probe the stability of scaling behavior, we performed a supplementary analysis of the local growth exponent β as a function of scale using sliding-window log–log fits (see Supplementary Materials, V18). This analysis revealed that synthetic systems exhibit predominantly negative β-gradients ($d\beta/d\log(k) < 0$), consistent with concave growth and progressive saturation. In contrast, the TRIBE representation shows mixed-sign behavior with both positive and negative β segments, indicating a non-monotonic scaling trajectory. This suggests that, unlike synthetic systems, TRIBE exhibits a transitional regime in which dimensional expansion accelerates before saturation. These results do not alter the primary growth–saturation finding but further support the interpretation

that TRIBE operates under stronger representational constraints.

3.2 Quantitative Comparison

Table 2 summarizes key metrics for all systems.

Table 2: Quantitative Comparison of Dimensionality Metrics

System	Growth Rate	Sat. Ratio	Compression	Peak D_{eff}
TRIBE	0.232	0.921	0.490	4.41
Hierarchical	0.820	1.000	0.907	45.35
Correlated	0.731	1.000	0.558	27.92
Sparse	0.430	1.000	0.748	37.38
Manifold	0.817	1.000	0.900	45.01
Mean	0.606	0.984	0.741	32.13
SD	0.262	0.035	0.189	17.24

Key findings:

- **Growth rates vary 4-fold**: From 0.23 (TRIBE) to 0.82 (hierarchical)
- **TRIBE saturates early**: Saturation ratio of 0.92 vs. 1.00 for synthetic systems
- **TRIBE is most compressed**: Only 49% of ambient dimensionality utilized

3.3 Growth–Saturation Structure

Most systems showed a three-phase structure:

1. **Low-dimensional local regime** ($k < 20$): Limited by small sample size
2. **Growth phase** ($20 < k < 200$): Dimensionality increases with neighborhood size
3. **Saturation phase** ($k > 200$): Dimensionality plateaus or saturates

TRIBE exhibited unique behavior: peak dimensionality occurred at $k = 200$, followed by a slight decline (Fig 2). This decline is modest (remaining within 90% of peak) and likely reflects numerical saturation effects rather than a distinct structural regime.

3.4 Cross-Domain Alignment

After normalization, dimensionality curves aligned strongly across systems (Fig 3a). The mean pairwise alignment was $r = 0.898$, with hierarchical and manifold showing near-perfect alignment ($r = 0.999$). Importantly, this alignment emerges after within-system normalization and should be interpreted as similarity in curve shape rather than equivalence of underlying representational

Figure 2: Normalized dimensionality curves showing saturation behavior. The 90% threshold line indicates saturation onset. TRIBE (navy) shows earlier saturation than synthetic systems.

geometry or dimensional scale. An average correlation of $r \approx 0.90$ corresponds to approximately 81% shared variance, indicating strong but not complete alignment across systems.

Before normalization, dimensionality curves differ substantially in absolute scale across systems (see Supplementary Figure S2). These differences reflect system-specific dimensional bounds and variance structure. After normalization, however, the curves collapse onto a shared growth–saturation profile (Fig 3), indicating that the observed alignment is not trivial but emerges after accounting for scale differences between systems.

Table 3 shows all pairwise alignment values.

Table 3: Pairwise Alignment Values (Pearson r)

System 1	System 2	Alignment
Hierarchical	Manifold	0.999
Hierarchical	Correlated	0.984
Correlated	Manifold	0.984
TRIBE	Correlated	0.915
Sparse	Manifold	0.878
Hierarchical	Sparse	0.877
TRIBE	Hierarchical	0.830
TRIBE	Manifold	0.829
Correlated	Sparse	0.781
TRIBE	Sparse	0.464

The only poor alignment involved TRIBE–sparse ($r = 0.46$). This deviation likely reflects

(a) Alignment heatmap showing pairwise correlations.

(b) Normalized curves aligned across systems.

Figure 3: Cross-domain alignment analysis.

differences in sparsity structure and effective dimensional compression between systems.

3.5 TRIBE-Specific Analysis

TRIBE representations showed distinctive properties (Fig 4):

(a) Dimensionality growth with error bars.

(b) Log-log relationship.

(c) TRIBE vs synthetic systems.

Figure 4: TRIBE-specific dimensionality analysis.

- **Low peak dimensionality**: $D_{\text{eff}} = 4.41$ (vs. 28–45 for synthetic)
- **Early peak**: $k_{\text{peak}} = 200$ (vs. $k = 500$ for synthetic)
- **Decline after peak**: D_{eff} decreases slightly for $k > 200$
- **High compression**: Only 49% of ambient dimensionality utilized

The power law fit for TRIBE in the growth phase yielded exponent $b = 0.23$, indicating sublinear growth.

3.6 Negative Results from Alternative Metrics

To ensure the dimensionality-based findings were not artifacts, we performed extensive negative control analyses:

- **V8: Dynamical torsion (χ)** – Mixed signs across regimes; no consistent alignment
- **V9: Curvature (κ)** – Independent from χ (max $r = 0.27$); no robust alignment
- **V10: Residual structure (ξ)** – Non-Gaussian structure present but model-dependent
- **V11: Residual invariance** – Heavy-tailed residuals were artifacts, not intrinsic
- **V12: Structural invariance** – Dimensionality $D = 9.00$ is invariant but domain-general

Figure 5 shows that alternative metrics failed to show consistent alignment.

(a) Comparison of metrics across systems.

(b) Cross-domain saturation comparison.

Figure 5: Failure of alternative metrics to show alignment.

3.7 Null Model Evaluation

To assess whether the observed growth–saturation profile may reflect generic statistical properties of the dimensionality estimation procedure, we constructed a null model with controlled characteristics:

Null Model Specification:

- **Distribution**: Multivariate Gaussian
- **Sample size**: $n = 2000$ (matching other systems)
- **Dimensionality**: $d = 9$ (matching TRIBE)

- **Eigenvalue spectrum**: Matched to TRIBE's eigenvalue distribution to isolate the effect of spectrum shape while controlling for scale

The same analysis pipeline was applied: k-nearest neighbor construction, participation ratio computation, within-system normalization, and curve alignment.

Results: The null model exhibits a growth–saturation profile qualitatively similar to the original systems: dimensionality increases with neighborhood scale before saturating. However, alignment with other systems was weaker than observed among the original five systems. Specifically, the null model's alignment with TRIBE was $r = 0.72$ (vs. mean $r = 0.85$ for original synthetic systems), and alignment with the broader system set was $r = 0.68$ (vs. $r = 0.90$ mean across original systems).

These results suggest that some aspects of the growth–saturation profile may reflect general statistical structure inherent to participation-ratio dimensionality estimation in bounded high-dimensional spaces. However, the weaker alignment of the null model compared to original systems suggests that the stronger alignment observed among original systems is not fully explained by generic estimation properties and may reflect additional shared structure. This interpretation is qualified by the limited scope of the null model evaluation; a comprehensive assessment would require additional null models varying spectrum shape, dimensionality, and sampling density systematically.

4 Discussion

4.1 4.1 Characterizing the Growth–Saturation Profile

The present results establish a reproducible growth–saturation profile in effective dimensionality across the systems analyzed, as well as strong alignment of these profiles after within-system normalization. These findings are descriptive and characterize how dimensionality evolves with neighborhood scale under a consistent estimation framework.

However, the current analysis does not establish that this profile is unique, mechanistically determined, or specific to the systems considered. In particular, because participation-ratio dimensionality is computed from local covariance structure in bounded high-dimensional spaces, similar growth–saturation behavior may arise under generic conditions.

This pattern was robustly observed across 5 diverse systems, with normalized curves showing mean alignment $r = 0.898$. The pattern is consistent with:

- **Hierarchical organization**: Local structure is embedded in lower-dimensional subspaces that gradually integrate
- **Constrained capacity**: Representational systems cannot utilize all available dimensions
- **Manifold structure**: Data lies near a lower-dimensional manifold that is progressively sampled

The broken power law model (V15) provided the best fit for TRIBE:

$$D_{\text{eff}}(k) = a \cdot k^b \cdot \mathbb{I}(k < k^*) + c \cdot \mathbb{I}(k \geq k^*) \tag{7}$$

with $R^2 = 0.97$, supporting the growth–saturation transition at $k^* \approx 200$.

TRIBE showed distinctive compression (compression ratio = 0.49) compared to synthetic systems (0.56–0.91). Possible explanations include:

1. **Model constraint**: TRIBE-derived representations may be compressed due to the specific constraints of the representational framework
2. **Model bottleneck**: TRIBE v2 operates on a fixed vocabulary and may not require full representational capacity
3. **Stimulus limitation**: The 11,522 model predictions may undersample the full stimulus space, limiting observed dimensionality
4. **SGP node specificity**: The 9 SGP cognitive domains (broca, wernicke, TPJ, PFC, DMN, limbic, sensory, ATL, premotor) may define a constrained representational space

We emphasize that these are correlational observations; no causal conclusions can be drawn from the present analysis.

4.2 4.2 Speculative Mechanisms (Unvalidated)

The following mechanisms are speculative and unvalidated. They represent plausible post-hoc interpretations and should not be considered explanatory or causal accounts.

One possible interpretation is that the observed growth–saturation profile may arise from several factors:

1. **Information accumulation**: This may reflect the fact that as neighborhood size increases, more variance directions are captured, but variance is distributed across dimensions with decreasing eigenvalues
2. **Redundancy saturation**: A potential explanation is that at small k, each new neighbor adds substantial new variance, while at large k, new neighbors are increasingly redundant with existing samples
3. **Finite sampling of manifold**: If data lies on a d-dimensional manifold in ambient space $D > d$, then $D_{\text{eff}} \to d$ as $k \to \infty$ (if sampling is uniform)
4. **Curse of dimensionality**: High-dimensional spaces are sparse; neighborhoods of fixed k may become less representative as ambient dimension increases

5. **Signal-to-noise saturation**: Eigenvalue spectra typically decay, so additional samples may contribute less to higher-order statistics

Preliminary analysis of scale-dependent exponent dynamics suggests that these growth–saturation profiles may reflect an underlying constraint-gradient mechanism, a direction we leave for future work.

4.3 4.3 Potential Neuroscience Implications

Because the TRIBE dataset is model-derived rather than an empirical neural measurement, these observations should not be interpreted as evidence of cortical organization. Instead, they reflect properties of a biologically inspired representational model and motivate future validation using empirical neural data.

These findings connect to several themes in systems neuroscience:

1. **Cortical hierarchy**: The primate cortex exhibits hierarchical organization from sensory to association areas [Markov et al., 2013]. One possible interpretation is that this hierarchy may be reflected in scale-dependent dimensionality, with lower areas showing more compressed representations.

2. **Dimensionality reduction in fMRI**: Resting-state fMRI reveals low-dimensional functional connectivity patterns [Margulies et al., 2016]. This may suggest a complementary perspective on how dimensionality varies with spatial scale.

3. **Coding efficiency**: Neural representations may optimize for metabolic efficiency [Chung et al., 2019], potentially leading to compressed codes that sacrifice orthogonality for sparsity.

4. **Representational geometry**: Recent work emphasizes the importance of representational geometry (not just dimensionality) for understanding brain–computational relationships [Kriegeskorte and Kievit, 2013].

The early saturation observed in TRIBE is consistent with the hypothesis that model-derived cortical representations may reach effective capacity at relatively small integration scales. This may reflect constraints on representational capacity in the model framework, rather than properties of biological neural systems.

4.4 4.4 Null Model Considerations and Open Questions

A key limitation is that the present study does not fully evaluate null models tailored to the dimensionality estimation procedure itself. While alternative geometric and dynamical metrics did not reproduce the observed alignment, controls such as isotropic Gaussian systems, covariance-randomized data, or neighborhood-shuffled structures were not exhaustively tested.

Our null model evaluation (Section 3.6) provides initial evidence that the growth–saturation profile may partially arise from generic statistical structure of participation-ratio estimation. However, the weaker alignment of the null model compared to original systems suggests that additional shared structure remains unexplained. A comprehensive assessment would require additional null models varying spectrum shape, dimensionality, and sampling density systematically.

Open questions include: (1) Whether the observed profile reflects non-trivial structure or generic estimation properties, (2) Whether other representational systems show similar profiles, and (3) Whether the pattern holds in empirical neural data.

4.5 4.5 Limitations and Future Directions

Several limitations should be considered:

1. **Limited real-world datasets**: TRIBE is a computational model rather than direct neural recordings. While it approximates cortical activation patterns, model-specific architectural constraints may influence observed dimensionality. Future work should validate whether scale-dependent growth–saturation emerges in empirical data (e.g., fMRI, electrophysiology).

2. **Dependence on model-derived representations**: Results may not generalize to empirically measured neural activity [Galletti and Fattori, 2001]

3. **No causal mechanism established**: We characterize patterns but do not explain their origin

4. **k-NN metric sensitivity**: Results depend on the choice of Euclidean distance; other metrics may yield different patterns

5. **Synthetic system specificity**: The synthetic systems are designed to span plausible geometries but do not exhaustively sample the space of possibilities

Additionally, the present study does not establish a causal mechanism underlying the observed growth–saturation behavior. While the consistency of the pattern across systems suggests a general organizing principle, further work is required to determine whether this structure arises from specific generative processes, optimization constraints, or statistical properties of high-dimensional data.

Future work should test the extent to which this pattern generalizes to empirically measured neural data and other real-world representational systems.

5 Conclusion

We characterize scale-dependent dimensional growth with bounded saturation as a consistent structural pattern observed within the present analysis. The normalized dimensionality profile $D_{\text{eff}}(k)$ shows strong cross-domain alignment (mean $r = 0.898$), suggesting a shared normalized multiscale dimensionality profile within the systems analyzed.

While qualitative structure is shared, quantitative differences reflect system-specific constraints on representational capacity. TRIBE-derived cortical representations show pronounced compression ($D_{\text{eff}} \approx 3$–5) and early saturation, distinguishing them from synthetic systems with similar ambient dimensionality.

These findings provide a framework for characterizing representational geometry across scales, with applications to computational neuroscience, machine learning, and complex systems analysis.

Future work should test the extent to which this pattern generalizes to empirically measured neural data and other real-world representational systems.

Data Availability

Analysis code and results are available at:

`https://github.com/urmt/SGP-Tribe3`

All analysis code is version-controlled, and the full pipeline (V8–V22) can be traced through repository history for reproducibility.

Raw data and processed results are stored in:

`manuscript/v{12-22}/`

Analysis Pipeline Versions

This manuscript synthesizes findings from analysis pipelines V8–V17:

- **V8**: Dynamical torsion across regimes (negative result)
- **V9**: Normalized curvature analysis (negative result)

- **V10**: Residual structure analysis (model-dependent)
- **V11**: Residual invariance test (artifacts identified)
- **V12**: Structural invariance ($D = 9.00$ invariant)
- **V13**: Effective dimensionality (TRIBE $D_{\text{eff}} \approx 3$)
- **V14**: Scale-dependent fits (power law for TRIBE)
- **V15**: Extended scale analysis (saturation at $k \approx 400$)
- **V16**: Cross-domain comparison (4/5 systems show growth–saturation)
- **V17**: Normalized alignment (mean $r = 0.898$)
- **V18**: Beta scaling analysis (phase diagram and constraint gradients)
- **V19**: Law testing (no simple universal decay law)
- **V20**: Bilinear phase model (universal model found)
- **V21**: Normalized law testing (parameter collapse fails)
- **V22**: Raw spectral analysis (low effective dimensionality)

V18 — Beta Scaling Analysis (Supplementary)

We analyzed the scale-dependent growth exponent $\beta(k)$ using sliding-window log–log regression across k ranges. Results show that synthetic systems exhibit consistent negative β-gradients, while TRIBE exhibits mixed-sign gradients indicating a transitional scaling regime. Full results, plots, and derived metrics are available in: `manuscript/v18_beta_analysis/`

V22 — Raw Spectral Analysis

We performed spectral decomposition on the full TRIBE dataset ($n = 11,522$ stimuli) to characterize intrinsic dimensionality across representational domains. For each domain (SGP nodes, streams, edge weights), we computed the covariance matrix across all stimuli and extracted eigenvalues.

Key findings:

- **SGP Nodes** (9 dimensions): Effective rank = 3.22, Participation ratio = 2.28
- **Streams** (5 dimensions): Effective rank = 2.01, Participation ratio = 1.53
- **Edge Weights** (9 dimensions): Effective rank = 2.31, Participation ratio = 1.63

Despite the high-dimensional representation space (up to 9 dimensions), the effective dimensionality is remarkably low (2–3), consistent with the manifold hypothesis and low-dimensional neural coding. These results complement the neighborhood-scale analysis by demonstrating that TRIBE representations occupy a low-dimensional subspace even at the population level. Full results and figures are available in: `manuscript/v22_raw_spectral/`
